Chapter 6

GRAIN SIZE ANALYSIS AND TEXTURAL CLASSIFICATION

Sediment texture refers to the proportions of sand, silt and clay or the proportion of size fraction below 2000 micrometers (2mm) in a unit mass of sediment (Ivara, 1999). Texture also gives a clear picture of size, shape and mutual relationships existing among different particles of the sediments. Grain size distribution is considered as a potentially informative and fundamental property of the sediments. Knowledge of grain size is often essential to understanding the temporal and spatial changes of sediment and their bearing on depositional environments. Grain size studies on shallow marine sediments has clearly demonstrated that they are not only reliable indicators for their environment of formation but also provide in depth insight of the regional hydrodynamics which also includes patterns of transport and deposition of the sediment (Petschick et al., 1996; Preda and Cox, 2005).

The grain size distribution in sediments is controlled by factors that includes channel morphology, source materials, process of weathering, abrasion and corrosion of the grains and sorting processes during transport and deposition. The identification of the source and depositional areas of sediments is important in understanding the evolution and current behaviour of any sedimentary systems. Textural characteristics and compositional properties of sediments are important criteria in determining the sedimentary provenance.

The characteristics of texture size distribution of sediments are related to the source materials, processes of weathering, abrasion and corrosion of the grains and sorting processes during transport and deposition (Mishra, 1969; Patro et al., 1989; Williams et al., 1978; Forstner and Wittmann, 1983; Seralathan, 1979, 1988; Samsuddin, 1990; Padmalal and Seralathan, 1991; Padmalal, 1992; Joseph et al., 1997; Rajamanickam and Gujar, 1984, 1985, 1997; Rajaguru et al., 1995). The understanding on textural characteristics of sediment is relevant in sedimentological studies and it receives valuable attention in recent decades. Grain size analysis is also one of the most important natural properties of sediment and commonly used parameter for sedimentological studies (Riyaz, Ahmad mir and Jeelani, 2015). The fundamental property of sediments that affect the transportation, entrainment and the deposition is the is the grain size. Grain size distribution of the sediments are considered as the sub-populations which represents the transportation of sediments by the process of saltation, rolling, and suspension (Inaman, 1952). The textural attributes of sediments are strongly affected by considerable factors, which include the composition at

the source area, length, climate and energy of the transporting medium and the redox condition at the environment of deposition (Fralick and Kronberg, 1997).

GRAIN SIZE PARAMETERS

The sediment textural attributes including the Mean (Mz), standard deviation (σ 1), skewness (SK1), and kurtosis (KG) are widely used parameters in reconstructing the depositional environment of sediments and sedimentary rocks (Komar 1998; Poppe and Elison, 2007). The depositional mechanism/processes of transport and size parameters in sediments are related to each other. Several studies related to ancient and modern sedimentary environments is also established (Itam et al., 2018; Chinna Durai et al., 2017; Temitope, 2016; Ganesh et al., 2013; Babu et al., 2007; Angusamy and Rajamanickam 2006). The knowledge on textural parameters and the sediment size is assumed to be one of the better tools to differentiate the various environments of depositional in recent as well as the ancient sediments (Kumar et al., 2010; Nordstorn, 1977).

The paleoclimate can also be interpreted from the grain size analysis of sediments (Beal et al., 1956). Large attempts are carried out by several sedimentologists in differentiating the sediments of various environments such as fluvial, fluviatile, and estuarine and other coastal environments over the years (Karuna Karudu et al., 2018; Mohtar et al., 2017; Bhattacharya et al., 2016; Manivel et al., 2016, Ramesh et al., 2015; Karuna Karudu and Jagannadha Rao, 2013). There are few grain size derived parameters which further helps in evaluation the sediment nature are mentioned below.

Mean Size (Mz)

The graphic mean size will emulate the overall average size of the sediments in the grain size spectrum or the central tendency. They also reveal the index of impacted energy to the sediment as a result of current velocity and turbulence of the medium of transport and also the energy circumstances of the environment of deposition (Durai et al., 2017; Itam et al., 2017; Sahu, 1964).

Standard Deviation (σI)

The graphic standard deviation in sediments will indicate the degree of sorting or the uniformity of particle size distribution. The parameter also describes the fluctuation in the aggressive energy, pontin towards the acceleration conditions of the depositing agent and also about its average velocity (Manivel et al., 2016). Spencer (1963) states that the standard deviation will reflect the energy condition of the depositional environment, without gauging the severity to which the sediment has been mixed. The higher value of standard deviation exhibits the selection of grains during the process of depositional as well as the transportation process. On the other hand, good sorting will represent the lower standard deviation values formed by the transport and deposits range of grain size due to the selective action of energy (Kamaruzzaman, 2002).

Skewness (SkI)

The skewness in sediments measures the asymmetric degree of the frequency distribution either predominant coarse or fine sediments in respect to the median (Xu et al, 2009). The variation pertaining to the energy conditions of the sedimentary process is reflected by the skewness (J. Siyi et al., 2014) and the skewness represents inversely proportional relation to the standard deviation (Cadigan, 1961).

Kurtosis (KG)

The graphic kurtosis is the measure used to describe the departure from the normal distribution. The kurtosis is a measure of broadness or peakedness of the curve and it would be afflicted due to the irregularities near the distribution at the center (Cadigan, 1961). Kurtosis is inversely proportional as well as an important function of the standard deviation (Riyaz et al., 2015). The kurtosis values are a consensus for normal distribution and the greater kurtosis values will point out that 50 percent of the average velocity within the centre is controlled by the fluctuation in the velocity.

GRAIN SIZE ANALYSIS IN GREAT RANN OF KACHCHH (GRK)

The present chapter deals with the subsurface sediment characteristics, wide scale palaeoevironmental conditions and development of lithostratigraphic framework of the Great Rann of Kachchh basin based on the two sediment cores (Dhordo and Berada). Two continuous cores, one from the central part of the basin (~60m depth) and the other from the marginal part of the basin. Banni plain (~51m) was raised. The cores were drilled by considering that, the central and marginal parts of the Great Rann basin would provide a basin wide record to reconstruct palaeoenvironmental conditions, provenance of the Rann sediments and its geological evolution throughout Holocene times. South marginal core in Banni plain can be assessed to estimate the role of the southern hillocks in the sediment budget of the Rann basin. A detail account on the regional geomorphic set-up is given in Chapter 2. A brief description of subsurface sediment characteristic with palaeoenvironmental conditions which existed in the Rann basin is given below.

DHORDO CORE

Particle size analysis on the selected 92 samples on regular interval of ~60 cm was carried out using Laser Diffraction Particle Size Analyser (Beckman Coulter). The samples were measured from the range of coarse sand to clay. All the samples were air dried and mildly crushed before treating them for carbonate and organic matter removal using mild 30% concentration of HCL (Hydrochloric Acid) and Hydrogen Peroxide following standard procedure (Folk, 1966). After removal of organics and carbonates, samples were treated with Sodium hexametaphosphate (NaPO₃)6 for dispersion before measurements and mixed well using shaker/sonicator. All the processed samples were then run on the particle size analyser and the data was processed and compiled using Gradistat program in Microsoft Excel (Blott and Pye, 2001).

Dhordo core show significant variations in its grain size variability; there appears cyclic sedimentation pattern of fining upward sequences with at least three cycles (Figure 6.1). The sand, silt sized particle abundance varies between 0.2 to 35 % and 60 to 85 % whereas; clay abundance ranges from 4.7 to 18 % (Table. 6.1). This points towards the mud dominated settings with variations in the energy of depositional environments. The calculation for all the parameters like mean grain size, kurtosis, mode, standard deviations and skewness are included and taken into consideration for better analysis of palaeoenvironmental and depositional conditions. Depositional conditions inferred from grain size variations in Dhordo core are as follows.

Grain size variations

<u>Greenlandian Stage (10.6 -6.5 kyr BP) (60 m - 22 m)</u>

During this stage, the sediment grain size shows fining upward sequence between 10.6 to 6.5 kyr BP with higher sand content (8-20 % rapidly fluctuating) specifically between ~10.6 to 9.3 kyr BP thereafter it decreases from ~9.3 toward 6.5 kyr BP (Figure 6.1 and Table 6.1). In contrast to sand, the clay sized particles clearly show inverse trend that is characterised by lower to higher abundance from bottom towards upward section of the core record during this stage. The grain size analysis shows increase in the sand and silt percentage till 50 m particularly at 53 m depth (Figure 6.1 and Table 6.1), however increment in clay percentage can be seen towards the bottom of the stage. The clay percentage dips to its minimum value at 41m depth (5%) which marks its lowest peak from this stage. The consistency from the clay data is noted from 41m depth upto 22 m. In fact,

constant increase in the clay percentage is noted throughout this stage. The silt is marked with little variation from 60 m to 35 m depths ranging from 85 to 75 percent. However, the consistency in the silt is noted from 35 m up till 22 m around ~82 percent on an average. The silt percentage on an average through this stage marks > 85 %, whereas the clay remains on the lower side with an average percentage of <10 through this stage. Overall sand is noted to remain less than 10 percent from 60 - 45 m depth, although it yet again reaches to ~10 percent from 43 m depth till the depth of 35 m. From 35 m sand tends to mark less than 1 percent continuing till 22 m. It can be concluded that this stage marks the dominance of silt with occasionally presence of clay and fine sand.

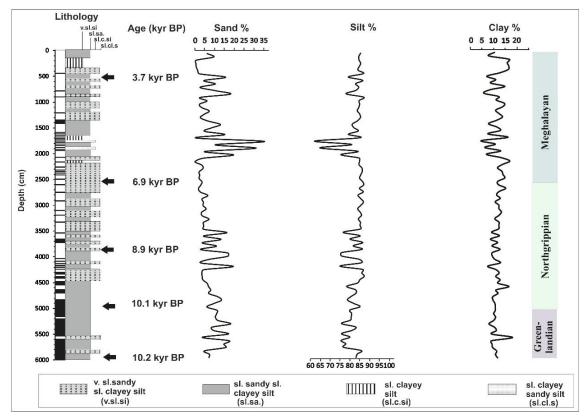

Figure 6.1. Grain size variation of sand silt clay along with lithological variation of the Dhordo core from GRK basin.

The texture noted from this stage varies between two textural classes which are very slightly sandy slightly clayey silt and slightly sandy slightly clayey silt. The percentage dominance of very slightly sandy slightly clayey silt from this stage is marked at 65 percent and the rest 35 percent is contributed by slightly sandy slightly clayey silt. The distribution of mode is dominated by unimodal followed by bimodal, trimodal and polymodal. The unimodal distribution of sediments is uniformly present throughout this stage which marks 52 percent of its presence whereas the stage is secondly dominated by bimodal which marks 35 percent of the total modal distributions. The polymodal mode distribution is poorly

present in this stage confirming its least presence from the core. Trimodal mode of distribution shares 11 percent in this stage.

Northgrippian Stage (6.5-4.2 kyr BP) (22 m - 7 m)

The sand content in the sediments increases to its maximum ~35 % (sl. clayey sandy silt) at 5.9 kyr BP and decreased upward to the lowest value of ~1% (sl. sandy sl. clayey silt) in the Dhordo core (Figure 6.1 and Table 6.1). The sand remains consistently on the lower side from 18 m to 11 m which contributes an average of ~4 percent. The silt from this stage ranges between 60 to 85 percent whereas the lowest peak in the silt percentage is noted at 18 m. The contribution of clay is constant which translate between 5 to 15 percent with an average of 8 percent. The clay shows its lowest percentage at 18 m depth which marks the lowest point of clay distribution from the entire Dhordo core. This change in grain size is abrupt and characterised by large scale fluctuations in all grain size denoting parameter (sand, silt and clay). The sediment characteristic in this stage shows three component system of unimodal, bimodal and trimodal sedimentation from the lower half of the stage where maximum sand content increases. From the upper half sand remains mostly bimodal and unimodal dominant (3.5 kyr BP) (~4.7 m) (Table. 6.1). The sediment sorting in this stage therefore suggests mixed and course sediment input to the basin.

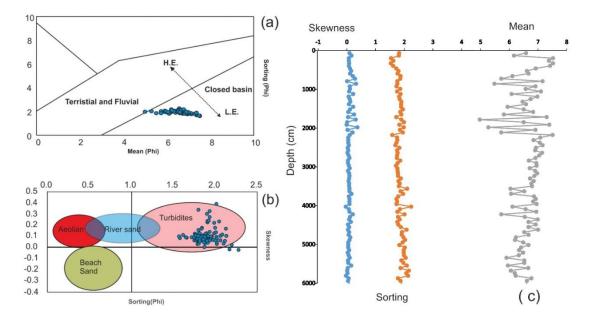

Figure 6.2. a) Diagram of mean grain size versus sorting of sediments from Dhordo core showing different energy and depositional environmental conditions (modified after Tanner (1991). b) Bivariate plot of grain-size distribution parameters of sorting and skewness showing energy of depositional environment. (after Bjørlykke, 2010). c) Line graphical presentation of mean, sorting and skewness along with the depths.

<u>Meghalayan Stage (4.2 kyr BP - recent) (7 m - 0 m)</u>

The topmost part of the core shows minor variation in the silt fraction where it remains on the higher side, overall silt fraction average to 80 percent from this stage. The sand fraction is noted with a minor dip from 5 to 3 m reaching to its lowest value of 0.5 percent. This stage is marked by highest clay dominated environments compared to entire

core records (least sand content) that indicate relatively lower energy of the environments (Figure 6.1 and Table 6.1). The sediments in this stage show characteristic light brown colour indicating the region might have been under a very shallow water column. The abundance of the marine microfossils in these sediments also advocates its active marine connectivity throughout this stage (Maurya et al., 2013). The dominance of unimodal mode of depositions is encountered throughout this stage contributing 80 percent participation of the total distribution.

Textural classification of Dhordo core

There are several textural classification schemes proposed over the years for textural classification. One of the primary schemes which covered the entire grain size of the sediments i.e. gravel to fine clay was first proposed by Folk and Warden, 1956. The fine-grained sediments textural classification was necessary for the gravel free environment deposition. One among the textural classification scheme was the classification proposed by Flemming, (1995). In the dominantly fined grained setting like Great Rann of Kachchh (GRK) textural classification based on wide range grain size (gravel to clay) do not appear to project the complete picture of sediment depositional condition and energy of its deposition. So, these setting needs more finer grain size classifications. Blot and Pye (2012) proposed scheme for the more finer sediment classification mainly dealing with the high silt dominated depositions. For this study Blot and Pye (2012) classification for the fine-grained sediments is taken into consideration due to the reasons discussed above (Figure 6.3 and Table 6.2).

The major textures recognised from the Dhordo core are (1) slightly sandy slightly clayey silt, (2) slightly clayey silt, (3) very slightly sandy slightly clayey silt (4) very slightly clayey sandy silt. Based on the grain size variation the sediment textures (Figure 6.3 and Table 6.2). The Dhordo core shows dominance slightly sandy slightly clayey silt texture where it covers 52 % from the entire core. The second vastly dominating texture recognised in the core is very slightly sandy slightly clayey silt where it dominates 32% from the entire core (Figure 6.3 and Table 6.2). The least occurring texture from the core are slightly clayey silt and very slightly clayey sandy silt contributing 15 and 8 % of presence respectively from the core. Based on the chronological division of the core Northgrippian Stage shows highest occurrence of sand up to ~35% (Figure 6.3 and Table 6.2). The texture translation towards more sandy texture i.e. very slightly clayey sandy silt from slightly sandy slightly clayey silt in this stage is a note worth change. The noted feature from the core is dominance of silt

contribution to the origin texture. This dominance can be noted from the consistence presence of silt percentage between 70 to 80 (Figure 6.3 and Table 6.2).

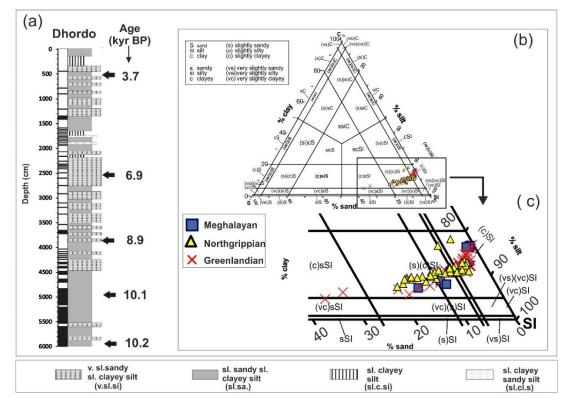

Figure 6.3. a) Lithology of the Dhordo core from GRK basin along with chronological age of the core. b) Triangular plot of grain size distribution in Dhordo core and its textural classification following Blott and Pye, (2011). c) Enlarge view of the textural attributes of GRK sediments in Dhordo core. Blue square box with cross showing sediments deposited during Meghalayan Stage, Yellow triangle reflects Northgrippian Stage and red cross showing Greenlandian Stage.

BERADA CORE

The Banni plain is a unique geomorphic entity of the Great Rann of Kachchh basin. The tidal waters from the Arabian sea do not reach the plain, as it is at slightly higher elevation than mean sea level and also due to chocking/filling of older creek, tidal channel/s which were active until a few thousand years ago (Kar et al., 1993, Maurya et al., 2013). The overall elevation of the Banni plain surface varies from 3 to 12m compared to the present day msl (Biswas et al., 2021; Kar et al., 2003). During the monsoon season (July to September), the low-lying area of Banni plain gets ponded by the fresh water from precipitation and northerly draining rivers from the Northern Hill range. The surface will remain covered under thin sheet of water column for few weeks to a month of two.

Interestingly, the overall evolution of Banni plain is not well understood due to lack of subsurface studies using sediment cores or geophysical surveys. Here in the present study, we present a high-resolution dataset on grain size analysis to decipher depositional condition of the Banni basin.

In the ~51 m deep sediment core, particle size analysis of 89 selected samples was carried out using Laser Diffraction Particle Size Analyser (Beckman Coulter). The sampling interval for the sedimentary core was ~60 cm. The samples were measured from the range of coarse sand to clay. Standard procedure proposed by Folk, 1966 was followed, in which the samples were air dried and mildly crushed before treating them with a mixture of 30% HCL (Hydrochloric Acid) and Hydrogen Peroxide for the removal of carbonate and organic matter. After removal of organics and carbonates, samples were treated with Sodium hexametaphosphate (NaPO₃)6 for dispersion and then mixed well using shaker/sonicator before measurements. The processed samples were then run on the particle size analyser and the data obtained was processed and compiled using Gradistat program in Microsoft Excel (Blott and Pye, 2001).

Figurer 6.4. Grain size variation of sand silt clay along with lithological variation of the Berada core from GRK basin.

Berada core shows significant variation in grain size. The core shows cyclic sedimentation pattern of fining upward sequences with at least three cycles (Figure 6.4 and Table 6.3). The abundance of sand and silt sized particle varies between 0.2 to 40 % and 60 to 85 % whereas, the clay ranges between 4.1 to 17 % (Table. 6.1). This points towards a

mud dominated settings with variations in the energy of depositional conditions. The lower part of the core from 40 to 50 m samples has been skipped for grain size analysis as it is fluvial dominated sediments and was not possible to carry out grain size analysis (Maurya et al., 2013). Calculation for all the parameters like mean grain size, kurtosis, mode, standard deviations and skewness are included and taken into consideration for better analysis of palaeoenvironmental and depositional conditions. Depositional conditions variation in Berada core are as follows.

The grain size analysis was carried out on selected samples from the Berada core to understand the variation in grain size and texture. The variation in the mean, median, mode sorting, skewness and kurtosis were carefully analysed.

Grain size variations

Fluvial sediments (51 m to 39.6 m)

The sediment from this unit can be categorize as coarse sand deposited under the influence of fluvial medium. It consists of pebbly poorly sorted, massive sands that occur between ~51 m to 39.6 m depth and it forms the bottommost part of the core and consist of unconsolidated brown coloured coarse sands. The sand comprises highly angular and unsorted grains. The sand fraction is very high with silt as minor component. The clay content is negligible in this portion of the core. Mineralogically, the sand fraction is dominated by quartz followed by feldspars. The general textural characteristics of the sand suggest fluvial origin. The angular and unsorted nature of the sand suggests a proximal source for the sediments. The source of the sand is more likely the rocky Mainland Kachchh to the south that exposes Mesozoic sandstones and limestones (Maurya et el., 2013; Khonde, 2014).

<u>Greenlandian Stage (10.6 -8.2 kyr BP) (60 m - 30 m)</u>

This section of the core is dominated by silt fraction with negligible fine sand fraction. The clay fluctuations with an average value of 12.5% can be noted following the trend of silt fraction. (Figure 6.4 and Table 6.3). The noted trend is encountered looking at clay parameter where it shows rhythmic fluctuation throughout this stage varying between 8% to ~17%. The mode of deposition varies in cluster manner between unimodal to bimodal implying the influence of bidirectional deposition (Table 6.3). The transition in skewness is noted in negative at ~38 m depth (Figure 6.5 and Table 6.3). The origin of the sediments are noted to be deposited under transgression. The mud dominated setting is noted from this

unit which suggests the deposition under lower but fluctuation energy conditions (Maurya et al., 2013; Khonde, 2014). The upward decrease in sand content and change in sediment colour from yellowish brown to greyish to blackish colour in the preceding section sediments, indicates increased water column and reduced energy condition which supports our interpretation of advancement of marine condition at the core site under estuarine to marshy settings.

Northgrippian Stage (8.2-4.2 kyr BP) (30 m - 4 m)

The clay fraction follows upwards increasing tread from 23 - 21 m thereby becomes consistent in the range of ~8%. Interesting change is noted from the mean ration of the unit which shows coarsening upwards trend up to ~26 m thereafter decline in the mean ratio is noted at ~24 m depth (Figure 6.4 and Table 6.3). The consistency in the sand fraction coupled with silt fraction is noted throughout this stage. These features can also be noted from the mode of deposition which also shows dominance in unimodal deposition. The particle size parameter is mainly dominated by silt/clay fraction where the increase in energy conditions is mainly reflected in silt fraction from 13 to 7 m depth (Figure 6.4 and Table 6.3). The sand mud ratio shows decreasing trend where sand reaches 0% at ~15 m thereafter sand increases to ~5 % at around ~9 m. The fine sand fraction continues to remain on the lower side of the average value (0.9 %). However, a little increase towards the average value mark is noted at 14 m and 11 m (Table 6.3) depths. Overall, the upward increase in sand fraction suggests the deposition under high energy conditions.

<u>Meghalayan Stage (4.2 kyr BP - recent) (4 m - 0 m)</u>

An abrupt change in the sand fraction is noted from this stage where the sand fraction reaches upto 40% at ~1 m depth (Figure 6.4 and Table 6.3) thus this stage is marked by the highest peak for the sand fraction. The clay remains on the lower side but consistent with an average of 10.4% from this stage. The silt fraction is noted with an average of ~78% from this stage reflects deposition under regressive sea where the deposition of sand particle appears to be abrupt. The dominance of unimodal mode of depositions is encountered throughout this stage contributing 80 percent of its distribution which quantifies for its supra tidal deposition (Tyagi et., 2012; Khonde, 2014, Sharma et al., 2020).

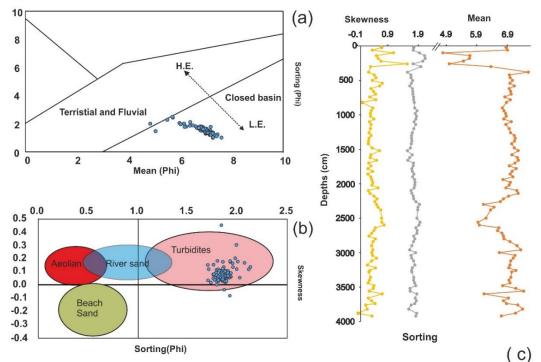

Figure 6.5. a) Diagram of mean grain size versus sorting of sediments from Berada core showing different energy and depositional environmental conditions (modified after Tanner (1991). b) Bivariate plot of grain-size distribution parameters of sorting and skewness showing energy of depositional environment. (after Bjørlykke, 2010). c) Line graphical presentation of mean, sorting and skewness along with the depths.

Textural classification of Berada core

The major textures recognised from the Berada core are (1) slightly sandy slightly clayey silt, (2) slightly clayey silt, (3) very slightly sandy slightly clayey silt (4) very slightly clayey sandy silt (5) slightly clayey sandy silt (Figure 6.6 and Table 6.4). Based on the grain size variation the sediment textures from the Berada core shows dominance of slightly sandy slightly clayey silt texture where it covers 55 % from the entire core (Figure 6.6 and Table 6.4). The second vastly dominating texture recognised in the core is very slightly sandy slightly clayey silt where it dominates 30% from the entire core. The texture slightly clayey sandy silt is 25 % present in the core (Figure 6.6 and Table 6.4). The least occurring texture from the core are slightly clayey silt and very slightly clayey sandy silt having 11 and 8 % presence respectively. (Figure 6.6 and Table 6.4). Based on the chronological division of the core Meghalayan Stage shows highest occurrence of sand up to ~40% (Figure 6.6 and Table 6.4). The texture translates towards more sandy texture i.e., very slightly clayey sandy silt from slightly sandy slightly clayey silt. The noted feature from the core is dominance of silty origin of texture which is due to constant presence of silt percentage between 55 to 75% (Figure 6.6 and Table 6.4).

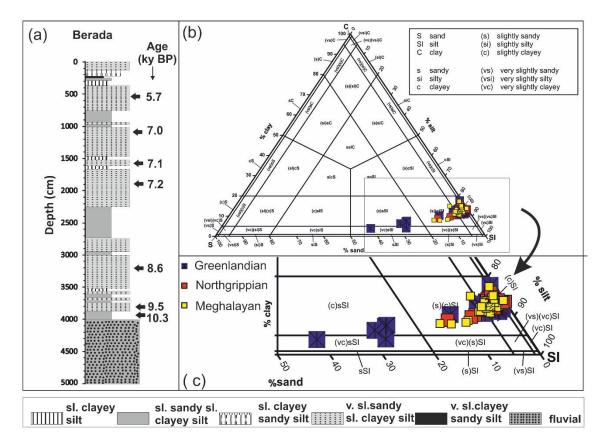

Figure 6.6. a) Lithology of the Berada core from GRK basin along with chronological age of the core. b) Triangular plot of grain size distribution in Berada core and its textural classification following Blott and Pye, (2011). c) Enlarge view of the textural attributes of GRK sediments in Berada core. Blue square box with cross showing sediments deposited during Greenlandian Stage, red square showing Northgrippian Stage and Yellow square reflects Meghalayan Stage.
